ABSTRACT

Thermal conductivity measurements were made for two copper, two gold and one silver-based polycrystalline rods and one copper-based single crystal rod in the temperature range 0.5 to 4 K. The polycrystalline rods were measured with each rod first being in a highly cold-worked condition and then in various stages of recovery brought about by annealing at temperatures up to 1000 K. From the total measured conductivity the lattice conductivity was extracted by calculating the electronic component using the Wiedemann-Franz law and electrical resistivity measurements. In none of the alloys did the lattice conductivity exhibit the temperature dependence expected from standard theory. Above 1.5 K, comparable experimental results of other workers, published only for copper alloys, agreed with the data presented here. Measurements below 1.5 K indicated an even larger departure from standard theory. It is the author's belief, that in the entire temperature region (0.5 to 4 K), the anomalies are contained in that part of the lattice conductivity which is limited by defect scattering. The anomalies in the silver and gold alloys, though basically similar to those in copper alloys, occurred at different temperatures and could be due to changes in the scattering of phonons by dislocations,

with an associated "characteristic" length of a few hundred angstroms. Changes in the temperatures of the anomalies were correlated with changes in phonon wavelength in different hosts. A preliminary electron microscope investigation of the copper alloys reported here does indicate the presence of a "characteristic" length, of a few hundred angstroms, though not associated with the dislocation structure.

th an associated "characteristic" length of a few :

wavelength in different hosts. A preliminary electron microscope investigation of the copper alloys reported here does indicate the presence of a "characteristic" length, of a few hindred angstroms, though not associated with the dislocation structure.

ACKNOWLEDGEMENTS

I wish to express my gratitude to the people without whom this thesis might not have been possible — Professor S.B. Woods, my research supervisor, for suggesting this project and for his patience, understanding and guidance throughout; Dr. P.S. Turner and Mr. J.A. Brunel for the electron microscope work; Mr. D. Gerritsen for technical help and a special word of thanks to Dr. J.A. Rowlands for numerous valuable discussions and constant encouragement.

Finally, I would also like to thank my wife-to-be Wicki whose moral support was invaluable in completing this thesis.

INTRODUCTION

Thermal conductivity measurements of some coldworked copper alloys have been reported recently by Kusonoki and Suzuki (1969), Charsley and co-workers (1968, 1971) and Mitchell et al (1971). These measurements indicate that the lattice thermal conductivity does not follow the expected quadratic temperature dependence in the range 1.5 to 4 K. Although the experimental results, of the above workers, were basically similar, various explanations have been put forward for the anomalous behaviour of the lattice conductivity. These anomalies have been attributed to: (a) a change in the electron-phonon interaction due to short electron mean free paths (Lindenfeld and Pennebaker 1962) or (b) a change in the scattering of phonons by (i) static dislocations and (ii) mobile dislocations. This thesis is an attempt to resolve the controversy by extending the measurements to lower temperatures (0.5 K) and to other noble metal hosts (silver and gold).

The various components of thermal conductivity are discussed in Chapter II along with a review of the previous work and proposed models. A description of the ³He cryostat, used for the measurements reported here, along with experimental details are given in Chapter III. Chapter IV is concerned with the choice

and preparation of specimens and all the thermal conductivity results are presented in Chapter V. A discussion of results with reference to various models follows in Chapter VI. Some suggestions for further work have been put forward in Chapter VII. The final chapter is a summary of the conclusions.

and preparation of specimens and all the thermal conductivity results are presented in Chapter V. A discussion of results with reference to various models. follows in Chapter VI. Some suggestions for further work have been put forward in Chapter VII. The final chapter is a summary of the conclusions.

CHAPTER II

THEORETICAL BACKGROUND

2.1 Introduction

The thermal conductivity λ of a metal may be divided into two components, the electronic conductivity, $\lambda_{\bf e}$, and the lattice conductivity, $\lambda_{\bf g}$. This thesis is primarily concerned with the measurement and analysis of the lattice thermal conductivity of metal alloys, at low temperatures. In a pure metal most of the heat is transported by the electrons and consequently it is extremely difficult to measure $\lambda_{\bf g}$. Point imperfections added to the host metal reduce the electronic component without substantially reducing the lattice component at low temperatures. The two components, $\lambda_{\bf e}$ and $\lambda_{\bf g}$, are then comparable and $\lambda_{\bf g}$ becomes a measurable quantity.

2.2 Separation of λ into Components

The total thermal conductivity λ can be written as a sum of its electronic and lattice components (Klemens 1958), so that

$$\lambda = \lambda_e + \lambda_g$$
 (2.1)

These two conduction processes are limited by various

CHAPTER II

(1.2)

- crion rocesses - a imited by various

scattering mechanisms that give rise to thermal resistances $W_e = \lambda_e^{-1}$ and $W_g = \lambda_g^{-1}$. It is then necessary to consider the various mechanisms that will scatter the electrons and phonons to arrive at the total thermal resistivity, and hence the total thermal conductivity. The electronic thermal resistivity is discussed in the next section and the lattice thermal resistivity is discussed in Sec. 2.2.2.

2.2.1 Electronic Thermal Resistivity

There are two major sources of electron scattering in alloys: imperfections and lattice vibrations. These give rise to thermal resistivities $W_{\rm eo}$ and $W_{\rm ei}$ where the subscript o denotes the imperfection induced (or residual) resistivity, and the subscript i the ideal (or lattice) resistivity. Below 4 K, the alloys reported here have a negligible $W_{\rm ei}$ because $W_{\rm eo}$ >> $W_{\rm ei}$. The electronic thermal conductivity is then given by the Wiedemann-Franz law (Klemens 1958).

$$\lambda_{e} = L_{o}T/\rho_{o} \tag{2.2}$$

where $\rho_{\rm O}$ is the residual electrical resistivity and L is the Sommerfeld value of the Lorenz number for elastic scattering = 2.445 \times 10⁻⁸ WNK⁻².

CANTE LET LO

2.2.2 Lattice Thermal Resistivity

The various scattering mechanisms for phonons are

- 1) specimen boundaries
- 2) electrons
- 3) dislocations
- 4) point defects and
- 5) interaction with other phonons.

The important sources of lattice resistivity in the alloys reported here, below 4 K, are electrons, $W_{\rm ge}$, and the strain fields surrounding dislocations, $W_{\rm gd}$. A physically plausible argument is presented below to show why $W_{\rm ge}$ has T^{-2} temperature dependence.

Using the dominant phonon approximation (Ziman 1958) one can write

$$\lambda_{q} \propto C_{q} v \ell$$
 (2.3)

where C_g represents the lattice specific heat, ℓ the mean free path of phonons and v the velocity of these phonons. Below 4 K, v can be assumed to be independent of temperature and $C_g \propto T^3$, so that only the temperature dependence of ℓ remains to be determined. The phonons can interact only with those electrons within the "thermal layer" around the Fermi surface. Since the "thermal layer" is $\sim kT$ in width, the number of electrons

interaction with other phonons,

The important sources of lattice resistivity in the alloys reported here, below 4 K, are electrons, Wge, and the strain fields surrounding dislocations, Wgd. A physically plausible argument is presented below to show why has T-2 temperature dependence.

Using the dominant phonon approximation (Ziman i) one can write

where C_g epresents the lattice specific heat, I the mean free path of phonons and v the velocity of these phonons. Below 4 K, v car be assumed to be independent of tempe ature and $C_g \propto T^3$, so that only the temperature of temperature of the remains to be determined. The phonons

cen interact only with those electrons within the wal layer" around the Fermi surface. Since the

available for scattering is proportional to T, so that $\ell \propto 1/T$. Using eqn. (2.3), $W_{\rm ge} \propto T^{-2}$ is obtained. This temperature dependence was experimentally verified by White and Woods (1954), Kemp et al (1957), White, Woods and Elford (1959) and Birch et al (1959), who deduced $\lambda_{\rm ge}$ in pure copper, silver and gold from measurements of the thermal conductivity of dilute alloys.

Klemens (1958) has shown that the lattice thermal resistivity arising from the scattering of phonons by dislocations also varies as T^{-2} . In his calculation, scattering by the dislocation core is shown to be negligible at low temperatures, the majority of the scattering being due to the long range strain field. In the range 4-20 K, thermal resistances varying as T^{-2} have been experimentally observed by Birch et al (1959), in alloys where a high density of dislocations had been introduced.

Since both $W_{\rm ge}$ and $W_{\rm gd}$ arise from phonon processes with the same frequency dependence, it can be assumed that they contribute additively to $W_{\rm g}$ (Klemens 1958), so that

$$W_{g} = W_{ge} + W_{gd}$$
 (2.4)

or

$$W_{q} = CT^{-2} + DT^{-2}$$
 (2.5)

The calculation of the total thermal resistivity for scattering processes of different frequency dependences is discussed in Appendix II.

EVERIABLY for scattering is proportional to T, as that if a lift. Using eqn. (2.3), W_{ye} T T is obtained.

This temperature dependence was experimentally varified by White and Noods (1954), Kemp et al (1957), White, Woods and Elford (1959) and Birch et al (1959), where dependence and gold from meanisometry of the thermal conductivity of dilutarious.

illemens (1958) has shown that the lattic thermal resistivity arising from the scattering of chopons by dislocations also varie:

Scattering by the dislocation core __ shown to the neglinestation at low temperatures, the majority of the scattering being due to the 'ong temperatures strain field.'. The range being due to the 'ong temperature strain field.'. The range 4-20 K, the mai resistar as yarying as T' have been experimentally observed by Birch et at (1959), in alleva

Since both Wg and Wid aring from phonon processes with the same trequency dependence, it can be assumed that they contribute additively to Wg (Klemens 1958).

(8.1)

2.2.3 Graphical Method of Separation

Using eqns. (2.1) and (2.2) the total conductivity $\boldsymbol{\lambda}$ can be written as

$$\lambda = L_O T/\rho_O + BT^2$$
 (2.6)

where

$$B \equiv (C + D)^{-1}.$$

Plots of λ/T against T would thus be expected to give a straight line with intercept L_O/ρ_O and slope B which will depend on the density of dislocations.

2.3 Previous Work

Mitchell et al (1971), Leaver and Charsley (1971) and Kusonoki and Suzuki (1969) made independent studies of λ_g , in the temperature range 1.5 to 4 K, on deformed and subsequently annealed copper alloys containing between 2 and 15 at. % aluminum. The thermal conductivity data measured by all three groups of workers was basically similar and showed a pronounced change in temperature dependence, or "kink", between 2 and 3 K. Although the three groups attributed this change to an effect in the lattice thermal conductivity, each advanced a different explanation for it. The models they used are briefly discussed in the next section.

2.4 Review of Models

The various models suggested can be discussed in three categories:-

- (1) Scattering of phonons by electrons (in the region where the electronic mean free path ≃ phonon wavelength) - Pippard effect (1957).
- (2) Scattering of phonons by static dislocations
 - (a) Dislocation 'dipole' model by Leaver and Charsley (1971).
 - (b) Dislocation rearrangement model of Ackerman and Klemens (1971).
- (3) Scattering of phonons by mobile dislocations
 - (a) Dislocation 'flutter' model as discussed by Ziman (1960).
 - (b) Resonance scattering by partial dislocations Kronmüller (1972).

2.4.1 Scattering of Phonons by Electrons

Pippard (1957) has shown that the electron-limited lattice thermal conductivity will depart from the usual \mathbf{T}^2 dependence when $\mathfrak{ql}_e \lesssim 1$ (where \mathfrak{q} represents the phonon wave vector and \mathfrak{l}_e the electronic mean free path). The inequality $\mathfrak{ql}_e < 1$ implies that the electrons do not travel sufficiently far between scattering events to 'sample' one complete wavelength of the

2.4 Review of Medels

The various models suggested can be discussed in three categories:-

- (1) Scattering of phonons by electrons (in the region where the electronic mean free path = phonon wavelength) Pippar effect (1957).
 - (2) Scattering of phonons by static dislocations
 - (a) Dislocation 'dipole' model by Leaver and Charsley (1971).
 - (b) Dislocation rearrangement model of Ackerman and Klemens (1971).
 - (3) Scattering of phonons by mobile dislocations
 - (a) Dislocation 'flutter' model as discussed by Ziman (1960).
- (b) Resonance scattering by partial dislocations Kronmüller (1972).

2.A.1 Scattering of Phonons by Electrons

lattice virbation. The interaction between phonons and electrons is thereby reduced and leads to an extra lattice conductivity proportional to T. Experiments by Zimmerman (1959) and Jericho (1965) on silver alloys, by Lindenfeld (1962) on copper alloys and by Archibald et al (1967) on potassium alloys (of comparable $\rho_{\rm O}$), do show an increase in the thermal conductivity below 2-3 K. Mitchell et al (1971) have interpreted their data, on cold worked and annealed copper alloys, also in support of Pippard's theory.

2.4.2 Scattering of Phonons by Static Dislocations

(a) Dislocation 'dipole' model

The scattering of phonons by the long range strain field of dislocations produces a T^2 variation of λ_g at low temperatures. However, the probability that a phonon will be scattered by a defect depends on the relative size of the defect and the phonon wavelength. As the temperature decreases the dominant phonon wavelength increases and the phonon scattering begins to be affected by the overlap of some of the dislocation strain fields. This overlap leads to a reduction in the scattering, as, on the average, the strain fields tend to cancel each other.

In the Leaver and Charsley (1971) model a fraction of the dislocations are assumed to be in a 'dipole'

lattice virbation. The interaction perween phonons and electrons is thereby reduced and leads to an extra lattice conductivity proportional to T. Experiments by simmerman (i) 100 and deriche 100 and possible of the comparable of the comparable (1967) on possible alloys (of comparable and possible and increase in the thermal conductivity bolom 25% whichell et al (1971) have interpreted their data, where cold worked and anneared copper alloys, also in support of pippard of theory.

1.2 Scattering of Phonons by Static Dislocations

(a Dislocation 'dipole' model

The stattering or phonons by the long range strain field of dislocations produces a Townstiation of A at low temperatures. However, the probably phonon will be scattered by a defect depends on the relative size of the defect and the phonor wavelength.

As the temperature decreases the dominant phonon wavelength length increases and the phonon scattering begins to be affected by the overlap of some of the dislocation eads to a reduction

arrangement. In the dipole configuration, two parallel edge dislocations of opposite signs are separated by distances small compared with other dislocation separations. Since the long range strain fields of the two dislocations in such an arrangement partially cancel, one expects a decrease in phonon scattering compared to that of two isolated dislocations. Leaver and Charsley (1971) assumed that dislocation dipoles would scatter phonons, which have a wavelength greater than n times the dipole separation, with $\ell = 0$ (n is an adjustable parameter and $\ell = 0$ is the phonon frequency). All other phonons would be scattered as for an individual dislocation, i.e. $\ell = 0$ (Gruner and Bross 1968).

Choosing values of d \approx 200-250 Å (from electron microscope data), n was varied to optimize the fit to the data. For d = 250 Å and n = 0.5, Leaver and Charsley found good agreement with experimental curves in the temperature range 2 to 4 K. Their calculations of λ_g below 2 K showed a plateau in λ_g /T against T plots around 1 K.

(b) Dislocation arrangement model

Ackerman and Klemens (1971) calculated the lattice thermal conductivity due to a dense array of dislocations. On the assumption that dislocations tend to rearrange themselves so as to minimize the free energy, they showed that this leads to a cancellation of the long range

orrengement. In the dips g.conviguration, w paralled edge dislocations of opposite signs are sopared to distances small compare with other is caused separations. Since the long range strain ries the two dislocations in such an arrangement of cancel, one expects a decrease in anonous scatt dompared to the two isolated signations. It is and Charsley (1971) assumed that dislocation and context phonons, which have a relength gramed than a times the dipol separation. It is then a times the dipol separation. It is adjustable paramet and usus the phonon requency on adjustable paramet and usus the phonon requency alistocation, i.e. In adjustable to their shonons would or cattered as for in adjustable paramet.

(b) Dislocation arrangemen model

Ackerman and Klemens) calculated the lattice

real conductivity due

strain field. This model though similar to the Leaver and Charsley model, is much less restrictive on dislocation arrangements and would lead to a slower deviation from a T² behaviour than the 'dipole' model.

2.4.3 Scattering of Phonons by Mobile Dislocations

(a) Dislocation-flutter model

So far the dislocation and its surrounding strain field have been treated as static entities. However, it is known that dislocations are not fixed to the medium but can move. This mobility should be taken into account in the analysis of scattering, for the incident phonon has a stress field which may cause the dislocation to move while scattering the incident phonon. Ziman (1960) has shown that the scattering width is proportional to the phonon wavelength, so that

$$W_{gd} \propto T^{-4}$$
.

To date, the only experiments which indicate such a strong temperature dependence of λ_g are measurements made by Jericho (1965) and Lindenfeld (1966).

(b) Resonance scattering by partial dislocations

In a face-centred cubic metal a dislocation may dissociate into two partial dislocations, separated by a stacking fault - a region across which the sequence

strain field. This model though similar to the mover and tharston model, is much asserteinve on our location arrangements and would dead to a slowed deviation from a T behavious that the 'dipole' model.

2.4.3 Scittering of Thonons by Mobile Distronti

(a) Distroation-flutter model

field have been treated as static entities. However is known that dislocations are not fixed to the part can move. This mobility should be take in the analysis of scarcering, for the incident of has a stress field which may cause the dislocation to nove while scattering the incident progner. That the scattering width is proportional the phonon wavelength, so that

canoidana D

of close-packed layers is disturbed. Kronmüller (1972) has calculated the vibrational frequencies of these partial dislocations to be 10^{10} to 10^{11} Hz which correspond to the dominant phonon frequencies at 1 K. Resonant scattering of phonons by vibrating partials can, therefore, produce a change in the phonon conductivity close to 1 K. The resonant frequency $\omega_{\rm O}$ is directly proportional to the stacking fault energy, and inversely to the stacking fault width (Kronmüller 1972) so that:

$$\omega_{o} = (2\gamma/m_{eff}d)^{\frac{1}{2}}$$
 (2.7)

where

 γ = stacking fault energy

d = stacking fault width

 $m_{eff} = effective dislocation mass$.

At resonance, the scattering of phonons would be enhanced and this would lead to a plateau in the lattice conductivity or, under special circumstances, a minimum. Thermal conductivity measurements on superconducting niobium single crystals have been interpreted by Anderson and Smith (1973) as indicating a resonant scattering of phonons around 1 K.

2.5 Need for Further Work

As various explanations existed for the anomalous behaviour of the lattice thermal conductivity of cold worked copper alloys, it was anticipated that extending the measurements down to liquid ³He temperatures would clarify the situation. Preliminary measurements on copper alloys, of the same type studied by others, yielded similar experimental data in the liquid ⁴He region, and enhanced conductivities in the ³He region. It seemed that measurements on other, cold-worked, noble metal hosts (where the phonon wavelengths were different) would be helpful.

2.5 Need for Further Wa

As various explanations existed for the anomalos behaviour of the lattice thermal conductivity of sola worked coppes alloys, is was sticips ad that extending the measurements down to liquid "He temperatures would clarify the situation. CHAPTER III

EXPERIMENTAL DETAILS

In order to measure the thermal conductivity of various metals and alloys, in the temperature range 0.5-4 K, a ³He cryostat was constructed. The design of the cryostat was similar to the one described by Archibald, Dunick and Jericho (1967), with a few modifications. Both the thermal conductivity and the electrical resistivity of a specimen can be measured, over the entire temperature range, in a single run.

3.1 Low Temperature Section

At all temperatures the main coolant is liquid ⁴He in a glass dewar, boiling under normal pressure. For measurements between 2 and 4 K, liquid ⁴He in a thermally isolated copper pot is cooled by reducing the pressure above it. For measurements below 2 K, a further stage of refrigeration is used; a pumped pot containing liquid ³He.

A cross-section of the low temperature part of the cryostat is shown in Fig. 1. It consists of three main sections:

- (i) a copper outer can,
- (ii) the ⁴He pot with an isothermal radiation shield, and

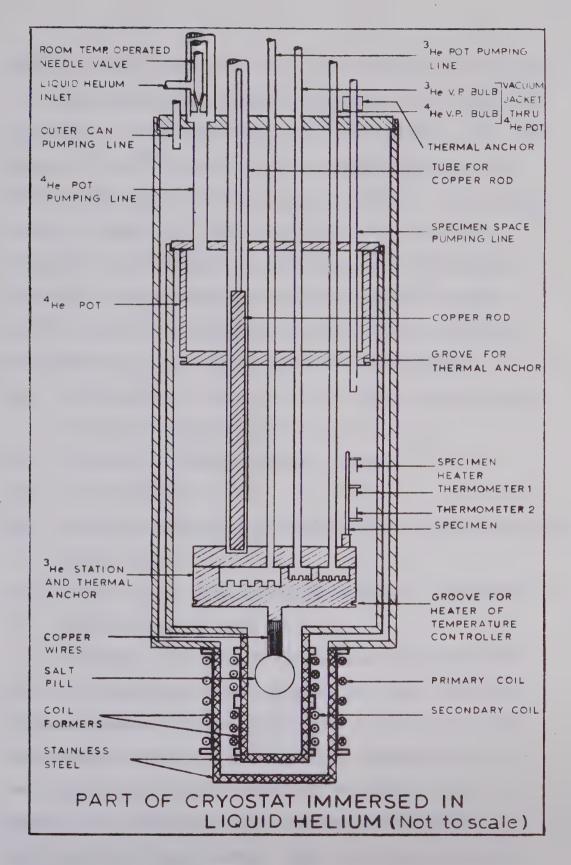

Fig. 1. The Cryostat.

(iii) the ³He station to which the specimen is soldered.

The outer can, cooled by immersion in a dewar of liquid ⁴He, can be evacuated, thereby isolating the ⁴He station. The ⁴He pot (a 150 c.c. copper pot) can be filled with liquid ⁴He and pumped to obtain temperatures between 1.2 and 4 K. Extending below the pot is a removable, brass inner can (enclosing the ³He station) which can be evacuated by a separate pumping system. The ³He station, a copper block with various chambers machined into it, is comprised of the following:

- (i) a ³He pot of capacity 3 c.c. which can be pumped to obtain temperatures down to 0.4 K,
- (ii) ⁴He and ³He vapour pressure bulbs,
- (iii) a specimen post,
- (iv) carbon resistors and a heater used for temperature regulation.
- (v) a salt pill, hung directly below the ³He station and isothermal with it.

Starting at the room temperature cryostat head, the electrical leads, including spares, pass down the specimen chamber pumping tube. The lower end of this tube passes through a brass block as shown in Fig. 1. The wires were wrapped around and varnished to a copper post, which was then soldered with Wood's alloy into the brass block. This block was normally covered with liquid ⁴He thus providing the first thermal

and the second second second

anchoring stage for the wires. The leads were again thermally anchored at the $^4{\rm He}$ pot and $^3{\rm He}$ station as indicated in Fig. 1. To keep the heat leak to the two stations small, #38 B & S manganin wire was used for all leads except the single current lead, for which #38 B & S copper wire was used. The free ends of the leads at the $^3{\rm He}$ station were soldered to electrically insulated pins embedded in a copper post. Electrical connections to the specimen, thermometers and heaters were made with coils of manganin wire, eight inches long (70 $\Omega/{\rm ft}$), ensuring that the thermal resistance in parallel with the specimen was large enough to prevent the heat flow through it from being disturbed.

The procedure used in cooling the cryostat was to introduce exchange gas (⁴He) at a pressure of several Torr into the outer and inner cans. Liquid nitrogen was used for pre-cooling. The dewar was then emptied and liquid ⁴He was then transferred into it, cooling the whole low temperature section (Fig. 1) to 4 K. The exchange gas was pumped out and the ⁴He pot filled with liquid through the needle valve, operated from the cryostat head at room temperature. The ⁴He pot and the ³He station were kept in thermal contact by lowering the movable copper rod and filling the tube around it with ⁴He gas at a pressure of several Torr.

Temperatures between 2 and 4 K were obtained by pumping

anchoring stars for the wires. The leads were again thermatly anchored at the He pot and he station us indicated in Fig. 1. To keep the Meat leak to the two stations small, #38 & & S mamorals were was used for all leads except the single current lead, for which

the ⁴He pot, controlling the pressure with a diaphragm manostat, and supplying a small amount of heat through the temperature controller. For measurements at lower temperatures the ³He pot was filled with liquid by introducing ³He at a pressure of about 250 Torr. The thermal linkage between the ³He and ⁴He stations was then "broken" and the ³He pot pumped through a room temperature needle valve to slightly below the required temperature. The temperature was regulated at a slightly higher value with a heater connected to a temperature controller.

3.2 Temperature Controller

The temperature controller is similar to the one described by Rochlin (1970). The circuit consists of an a.c. wheatstone bridge with a carbon resistance thermometer, as the sensing element, in one arm of the bridge. Regulation is provided by using the off-null signal, amplified by a phase sensitive detector, to control the power delivered to a heater placed in good thermal contact with the $^3{\rm He}$ station. This 1000 Ω heater, consisting of #42 B & S manganin wire (147 $\Omega/{\rm ft}$), was wound around the $^3{\rm He}$ station as shown in Fig. 1. Since the bridge was optimized for thermometer resistances between 500 and 5000 Ω it was necessary to use

menostal, o supplying a consult of the

two different thermometers to cover the entire temperature range (a 33 Ω Allen Bradley from 1.5 to 4 K and a 10 Ω one below 1.5 K). The resulting regulation of the 3 He station temperature was better than ± 0.5 mK.

3.3 Thermometry

3.3.1 Choice of Thermometers

A pair of fast responding thermometers are required for thermal conductivity measurements. possible choices are carbon or germanium resistance thermometers. The advantages of using carbon resistors are (i) they are cheap and (ii) their resistancetemperature characteristics can be fitted to a simple equation. The disadvantage is that they have to be recalibrated every run. In contrast, germanium thermometers are more expensive, fit a more elaborate equation, but once calibrated hold their calibration This excellent reproducibility was the major well. reason we chose to use germanium thermometers. thermometers were calibrated in the cryostat, as described later, and checked periodically.

It is important not to use too large a measuring current to avoid self-heating of the thermometers. Test experiments showed that at 10 μA no change in temperature occurred even at 0.5 K. Consequently, this

en la serion in review of land and land of the serion of t

.c on an a II

The state of the s

It is important not to use too

current was used for measuring the thermometer resistances at all temperatures. At all temperatures changes in thermometer resistance corresponding to temperature changes of 0.1 mK could be easily detected.

At temperatures below ~1 K extreme care has to be taken to ensure good thermal contact between the thermometer and the specimen. Below 1 K the pressure of the exchange gas in the thermometer capsule drops resulting in the temperature of the sensing element being different from the temperature of the thermometer casing. To circumvent this problem the specimen probe was thermally anchored to the thermometer leads as well as the thermometer case. A piece of #18 B & S gauge enamelled copper wire was wrapped around the case of the thermometer in a single layer and varnished. end of the wire was soldered to the specimen probe using non-superconducting solder (bismuth-cadmium). other end of the wire was used as a thermal anchor for the thermometer leads by winding and varnishing them to it.

The probes themselves were 2 cm long pieces of #14 B & S gauge bare copper wire, wrapped around the specimen in a single turn, transverse to the specimen axis, and soldered with non-superconducting solder.

Initially a different method was tried. A 1 mm diam. copper wire was etched carefully in concentrated acid

into a conical shape. Holes were drilled, in the specimen, at two convenient points (about 8 cm apart) and the thin end of the etched wire drawn through until it fit snugly. This would have allowed the probes to be left in place between runs, whilst the specimen was annealed, ensuring that the separation of the probes remained constant. This procedure was unsuccessful as below 1 K the pressure contact had too high a thermal resistance.

3.3.2 Vapour-Pressure Thermometry

The pressures of ⁴He and ³He in the vapour pressure bulbs were measured using two precision pressure gauges manufactured by Texas Instruments.

These gauges have a high sensitivity and reproducibility (±0.001 Torr.). Between 2 and 4 K temperature measurements were made by reading the vapour pressure of ⁴He and using the T⁵⁸ scale (Brickwedde et al 1960).

In order to prevent errors due to cold spots the vapour pressure sensing tubes were vacuum jacketed where they passed through the ⁴He pot. Below 2 K, the ⁴He bulb was evacuated and temperatures were obtained from ³He vapour pressure measurements using the T⁶² scale (Sherman, Sydoriak and Roberts 1964). In the overlap region, between 2 and 3 K, the pressures over the two

bulbs were read simultaneously and the corresponding temperatures were found to be the same within ± 0.1 mK.

Below 0.7 K thermomolecular pressure corrections, which are difficult to estimate accurately, have to be applied, so the range for $^3{\rm He}$ vapour pressure measurements was limited to 0.7 to 2 K. Using this combination, the T 58 scale for $^4{\rm He}$ and the T 62 scale for $^3{\rm He}$, temperatures were reproduced over the range 0.7 to 4 K with an accuracy of $^\pm{\rm 0.1}$ mK.

3.3.3 Paramagnetic Thermometry

Paramagnetic thermometry is based on the temperature dependence of susceptibility of an almost
non-interacting system of spins. The general equation
governing their behaviour is the Curie-Weiss law

$$\chi = \frac{C}{T - \theta} \tag{3.1}$$

where

C = Curie constant,

T = Temperature,

 θ = Weiss constant, and

 $\chi \equiv Susceptibility.$

Three different salts were tried in turn:

Weiss constant, and

- (b) Ferric Ammonium Alum.
- (c) Potassium Chrome Alum.

CMN is known to obey Curie's law down to ~0.01 K and probably somewhat below (Abel et al 1964). However, fairly sensitive methods of measurement are required because the material has a small Curie constant. Ferric ammonium alum was therefore tried as it has a large Curie constant. However, the salt is extremely unstable since it loses its water of hydration very easily. Finally, potassium chrome alum was tried.

The thermal and magnetic properties of potassium chrome alum are fairly well known below 1 K (Bleaney 1950, Daniels and Kurti 1954). The salt was used in the form of a sphere 7/8 inch in diameter. The ends of about 300 strands of enamelled #38 B & S gauge copper wire were embedded in the sphere to provide thermal contact with the ³He station as shown in Fig. 1. The salt and an epoxy mixture (Harrison 1968) were cast in a split teflon mould with a hole for the sheaf of wires. The exposed ends of the wires were then soldered to the specimen station about 2 inches from the salt sphere.

The susceptibility of the salt, as a function of temperature, was determined from the change in mutual inductance of a pair of concentric coils which surrounded the salt. Mutual inductance measurements were made using a 17 Hz inductance bridge (Pillinger, Jastrum and

imil' menomen server (d)

was determined fro

i neen L

Daunt 1958). The primary coil consists of 3000 turns of #38 B & S gauge enamelled copper wire wound on a teflon former which fitted closely over the narrow end (tail) of the outer can. Both the outer can and the inner can had tails (as shown in Fig. 1) made from nonmagnetic stainless steel tubing. The secondary coil, mounted on the tail of the inner can, was wound in two sections on a single former. Each section consisted of 4000 turns of #40 B & S gauge enamelled copper wire, wound in opposition and connected to reduce the total mutual inductance to as small a value as possible. Copper leads were used to make connections between the two coils and the mutual inductance bridge. A few extra turns on one half of the secondary or slight misalignment on assembly or cooling, made a considerable difference to the total mutual inductance of the coils which could result in the mutual inductance lying outside the range of the bridge. Consequently the range of the bridge was extended by a factor of ten by replacing the standard 5 mH plate coil in the bridge by a "home-made" mutual inductor of value about 500 mH.

To determine M_{\odot} , (the mutual inductance in the absence of the salt pill) the measured mutual inductance M for the system with salt pill in place is first plotted as a function of 1/T (T from 0.7 to 2 K) and

collection former which we see the properties of testing the see that the case of the case

this curve extrapolated to $T=\infty$ gives M_{\odot} . Then $M-M_{\odot}$ is proportional to the temperature dependent part of the susceptibility of the salt.

Since vapour pressure measurements were used to determine the absolute temperature T from 0.7 to 4 K, it was only in the range 0.4 to 0.7 K that the magnetic temperature T* had to be converted to the absolute temperature T. However, in this temperature region, the difference between T and T* for Potassium Chrome Alum is negligible (Cooke 1949).

3.3.4 Calibration of Thermometers

The thermometers were calibrated by mounting them on a specimen of high thermal conductivity, soldered to the ³He station. Fifty different temperatures of this station were maintained and measured as described earlier. The resistances of the two germanium thermometers were measured, in rapid sequence, at each temperature. The data were then fitted to an equation of the form used by Blakemore (1970).

$$\ln R = \sum_{i=0}^{n} A_{i} (\ln T)^{i}$$
 (3.2)

Chebyshev polynomials and double precision were used for sufficient accuracy and it was found that a value of n = 7 gave the best fit. A deviation curve of

temperature. The data were tren lifted to ... equals

(T_{cal} - T_{exp}) vs T_{exp} was plotted, where T_{cal} were the calculated temperatures using eqn. (3.2) and T_{exp} were the experimental temperatures. Since the deviation curves for the two thermometers were very similar the corrections applied were generally less than 1 mK. A table of R vs T at intervals of 0.1 mK was generated for each thermometer, so that thermal conductivity calculations could be made quickly while a run was in progress.

3.4 Measurement of Thermal Conductivity

Measurements of the thermal conductivity λ (T) were made in the steady state by passing a constant heat current Q down the specimen and measuring the temperature difference Δ T between two points. Then:

$$\lambda (T) = Q(\ell/a)/\Delta T \tag{3.3}$$

where ℓ is the length between thermometer connections and A is the cross-sectional area of the specimen.

Current leads to the two germanium thermometers were connected in series. The specimen heater, of 1500 ohms resistance, was made by winding #40 B & S gauge manganin wire on a 2 mm diameter insulated copper wire. This was attached to the specimen with Wood's alloy. Current leads to the heater from the ³He station were

superconducting (lead plated manganin wire), thus eliminating any corrections due to joule heating in them.

To measure the thermal conductivity at any given temperature T, the 3 He station was first stabilized at a temperature slightly below T. The specimen heater was switched on and the power adjusted to produce a reasonable Δ T. Generally Δ T was ≈ 150 mK at 4 K and ≈ 40 mK at 0.5 K. Both thermometers were read in rapid sequence and their temperatures recorded when they became steady. The heater was then switched off and the two temperatures recorded again in the steady state with Q = 0. This procedure was repeated twice to ensure that there was no appreciable drift in the temperature of the 3 He station. Then

$$\Delta T = (\Delta T)_2 - (\Delta T)_1$$
, where

- $(\Delta T)_2$ is the difference between the upper thermometer readings with the heater ON and OFF, and
- $(\Delta T)_1$ is the difference between the lower thermometer readings with the heater ON and off.

The temperature T is the mean temperature $(T_1 + T_2)/2$, where T_2 and T_1 are the temperatures of the upper and lower thermometers respectively with the specimen heater ON.

ΔΤ = (Δω) = ΤΔ

where T and T are the temporature 2 and Tall 2

The heat Q, produced by the heater, is determined by measuring the current I through and the potential V across the heater with a potentiometer. Then Q = IV. Measurement of the geometrical shape factor ℓ/A allows eqn. (3.3) to be applied to obtain λ (T).

3.5 Measurement of Electrical Resistivity

The electrical resistance of a specimen can be represented by

$$R = \rho \cdot (\ell/A)$$

where R is the electrical resistance, ρ the electrical resistivity and (ℓ /A) the geometrical factor. Since the electrical resistance and thermal conductivity of a specimen are measured in the same run using the same probes the shape factor remains the same for both measurements.

The electrical resistance was measured by passing a constant current through the specimen and a standard resistor and comparing the voltage drop produced across each. A four-terminal potentiometric arrangement was used to measure these voltages and currents were reversed to eliminate thermo-electric voltages. All the specimens used had a resistance of $\approx 400~\mu\Omega$ so that a current of 50 ma produced a voltage drop of 20 μV across the specimen. Since the smallest

detectable voltage was 100 nanovolts (nV), the resistance of the specimen could be measured to an accuracy of ½%. Manganin wires were used for the two potential leads and current to the specimen was carried down a copper lead. The return path of the current was through the cryostat.

The resistance of a specimen was generally first measured by immersing the specimen directly in liquid helium, in a storage dewar. The specimen was then mounted in the cryostat and its resistance measured at 4 K with ⁴He exchange gas present in the specimen chamber. For resistivity measurements below 1 K a different potentiometer was used with a galvanometer amplifier as the null detector. This increased the sensitivity and measurements could be made to the same accuracy using smaller currents.

3.6 Test of Apparatus

As a test of the apparatus, a test specimen with known conductivity and with a conductance similar to the alloys was required. Pure palladium (impurity content <12 ppm) was chosen, since in a pure material (a) the lattice conductivity could be assumed to be negligible compared to the electronic conductivity and (b) the low temperature limiting value of the ideal scattering process for electronic conductivity was known

known conductivity and with a conquetance similar to the alloys was required. Pure palladium (impurit

from the thorough work of Schriempf (1967, 1968).

The electrical resistivity of the specimen was measured over the entire temperature range, 0.5 to 4 K, and the data could be fitted by the expression

$$\rho = (6.01 + 0.003 \text{ T}^2) \times 10^{-8} \Omega \text{ cm}$$

which for the T^2 term is in good agreement with the data of Schriempf (1968) obtained above 2 K.

Schriempf's data (1967) can be expressed as $\lambda \rho/T = L_O' - BT^2$ where $L_O' = 2.48 \times 10^{-8}~W\Omega K^{-2}$ and B depends on ρ_O . In Fig. 2, $\lambda \rho/T$ for the palladium specimen is plotted against T^2 and fitted by a least squares procedure, yielding $L_O' = 2.48 \times 10^{-8}~W\Omega K^{-2}$, which is identical to Schriempf's value.

In Fig. 3, $\lambda \rho/T$ is plotted against T to provide a comparison with the plots for the alloys discussed later. The value for L_0 , obtained by fitting a straight line to this plot, is the same as that of Fig.2, within experimental error, although the extrapolation may have no physical justification. However, the data points fit the line smoothly with small scatter and without any sign of the "bumps" or "kinks" that are apparent in most of the alloy data.

CHAPTER IV

SPECIMENS AND THEIR PREPARATION

4.1 Choice of Specimens

The specimens used were fairly concentrated alloys in order to: (a) ensure that the electronic component of thermal conductivity was reduced, making it comparable with the lattice component and (b) make the total electrical resistivity practically temperature independent. The geometrical shape factor, ℓ /a, of each specimen was chosen so that the thermal conductance Q/ Δ T at 4 K was similar for all specimens. This required the resistance R of each specimen to be about 500 $\mu\Omega$. Phase diagrams (Hansen 1958) were checked to ensure that all alloys were within the solid solution region.

4.2 Specimen Preparation

A general procedure for preparing the specimens is outlined below. The pure materials were lightly etched and weighed. They were then melted either under vacuum or argon in either quartz or recrystallized alumina crucibles using a R.F. induction furnace. The resulting ingots were swaged or rolled to produce a rod of the required dimensions. A list of the specimens,

along with their residual resistivities and annealing temperatures, is given in Table 2.

4.2.1 <u>Cu</u>-10 at. % Al

This alloy was prepared by induction melting 99.999 % pure aluminum with OFHC copper in a 1/4" bore evacuated quartz tube. The resulting ingot was etched and then swaged in a number of stages, to 3.6 mm diameter. The specimen used was 10 cm long and was stored in liquid nitrogen to retain maximum cold-work.

4.2.2 <u>Cu</u>-30 at. % Zn

than the melting point of zinc (907°C) is much lower than the melting point of copper (1083°C). Consequently, in the process of melting in the induction furnace, a large proportion of the zinc was lost by evaporation. This problem was circumvented by starting with larger quantities. The copper was melted first and the zinc dissolved in it. Four cylindrical rods (½ " diameter) 10" long were cast into sand moulds at the American Brass Foundries, Edmonton. One rod was swaged down to 3/8" diameter, annealed, and then swaged to 1/4" diameter. The intermediate anneal was necessary to prevent cracking. Specimens 12 cm long and 4 mm in diameter were machined from this material.

4.2.3 <u>Cu</u>-30 at. % Zn Single Crystal

Two single crystals of brass were obtained from a commercial source (Windsor Metalcrystals 1973). One was a 1/2" diameter cylindrical rod and was spark cut into 1/8" square rods 6" long. The other, 1/8" diameter cylindrical 6" long was measured "as received".

4.2.4 Ag-2.1 at. % Al

This alloy was prepared by Seth and Woods (1970), in the form of a 1 mm diameter wire, and cold-worked by them in the process of drawing through dies, with intermediate anneals.

4.2.5 Gold Alloys

The Au-2 at. % Pt and the Au-10 at. % Ag alloys were prepared by induction melting materials of 99.999 % purity in recrystallized alumina crucibles under argon. Resulting ingots were etched and rolled into square rods of 4 mm² cross-section and 10 cm long.

4.2.6 Palladium

A 50 cm coil of 1 mm diameter pure palladium wire (impurity content <12 ppm) was obtained from a commercial source (Johnson Matthey, 1972) and used as the specimen.

6.2.3 Cm-30 at. & En Single Crystal

purity in recrystallized alumina ornerates uses argun.

Resulting ingots were a used and rolled and rolled and for a long.

4.3 Annealing

The specimens were annealed in a horizontal vacuum furnace whose temperature could be controlled with an uncertainty of ±5°C. All annealings were carried out for a period of 12 hours after which the specimen was allowed to cool gradually. The Cu-10 at. % Al specimens were annealed under vacuum but the rest of the specimens were annealed in an atmosphere of argon. To prevent excessive loss of zinc, the brass specimens were placed in a hollow brass cylinder with a loosely fitting cap and annealed under argon.

CHAPTER V

EXPERIMENTAL RESULTS

5.1 Graphical Presentation of Results

The thermal conductivity data for all alloys has been presented in Figs. 4 to 9 as plots of λ/T against T for reasons discussed in Chapter II, and to facilitate comparison with previous work. On these curves, departures from a horizontal straight line through L_0/ρ_0 (denoted by horizontal arrows) represent the contribution of λ_g to the total conductivity where, using eqns. (2.1) and (2.2)

$$\lambda_{G} = \lambda - (L_{O}/\rho_{O}) T . \qquad (5.1)$$

5.2 Copper Alloys

Data for the <u>Cu</u>-10 at. % Al and <u>Cu</u>-30 at. % Zn alloys, in various states of anneal, have been plotted in Fig. 4 and Fig. 5 respectively. In the temperature region 1.2 to 4 K the thermal conductivity points for the cold-worked and fully annealed states can be fitted to straight lines. However, this is impossible for the partially annealed states. Thus a least squares fit was made in two line segments (Mitchell et al 1971) giving rise to a "kink" in the plots, at a temperature

. 1 (09) d) - K = K

5.2 Copper Alloys

Data for the Cu-10 at. s Al and Cu-30 of alloys, is various states of anneal, b. new slotted in Fig. 4 and Fig. 5 respectively. In the temporature is to 4 K the thermal conductivity points for sally annealed states can be

 T_k , around 2.5 to 3 K (indicated by small vertical arrows). Below 1.2 K, thermal conductivity values depart from the T^2 dependence and so the data, in the region 0.5 to 1.2 K, appear as a "bump".

Fig. 6 is a plot of λ/T vs T for the 1/8" diameter Cu-30 at. % Zn single crystal. Square rods cut from the larger crystal yielded basically similar results. The lattice thermal conductivity of this specimen is slightly larger than that of the fully annealed Cu-30 at. % Zn alloy, but the onset temperature of the bump is the same (≈1.2 K).

5.3 Silver and Gold Alloys

A plot of Ag-2.1 at. % Al data (Fig. 7) indicates the presence of a "bump" at a slightly lower temperature (~1 K). Between 1 and 4 K the thermal conductivity points cannot be fitted to a straight line so that "kinks" appear at a temperature $T_k \approx 2.5$ K.

Data for the \underline{Au} -2 at. % Pt and \underline{Au} -10 at. % Ag alloys are presented in Fig. 8 and Fig. 9 respectively. Kinks are evident in the λ/T vs T plots at $T_k \approx 2$ K, which is lower than the values of T_k for copper and silver alloys. The onset temperature of the bump, T_k , appears to be just below 0.8 K. However, unlike the situation in the silver and copper alloys, the values of

The around 2.5 to 3 K (indicated by small vertical sarrows). Below 1.2 K, thermal conductivity values depart from the T² dependence and so the data, in the region 0.: To 1.2 is access as as a constant.

(*1 %). Berween' and 4 % the thermal conduct 'y points cannot be fitted a limited a limit of the spylear at a temperature T = 2.5

Nata for the A1.2 $\,$ % Pt and Au-10 at. alloys are presented in Fig. 7 and Fig. 9 respectively. The same eviden in the A/T vs T plots at $T_{\rm K} \approx 2$ K, a is lower that the values of $T_{\rm K}$ for copperant elloys.

 λ_g in the cold-worked condition do not approach the λ_g values of the annealed state at the lowest temperatures.

The residual resistivity of each specimen was measured in various states of anneal and the values are listed in Table 2. The residual resistivity of the Au-2 at. % Pt alloy increased from 1.2 to 2 $\mu\Omega$ -cm on annealing, and dropped to 1.8 $\mu\Omega$ -cm on re-rolling. This puzzling phenomenon has been observed previously by Birch et al (1959). Thermal conductivity measurements were made in all three states of anneal.

The measured thermal conductivities and lattice conductivities calculated from them, using eqn. (5.1) with $L_{_{\scriptsize O}}=2.445\times10^{-8}~\text{W}\Omega\text{K}^{-2}\pm1$ %, are listed as a function of temperature in Tables 3 to 18. Since the measured Lorenz ratio, $\lambda\rho/T$, for the cold-worked gold alloys was less than $L_{_{\scriptsize O}}$ at certain temperatures, the calculated $\lambda_{_{\scriptsize G}}$ values, at these temperatures, are negative.

Ag in the cold-worked condition do not walves of the annealed state at the atures.

CHAPTER VI

DISCUSSION OF MODELS AND EXPERIMENTAL RESULTS

The thermal conductivity results of copper alloys will first be discussed. In section 6.1 it is shown that the anomalies lie in $W_{\rm gd}$ (phonon scattering by dislocations) and in section 6.2 the copper alloy data is discussed with reference to various existing models. Results for the silver and gold alloys are discussed in section 6.3 and finally, in section 6.4, the temperatures at which the anomalies occur are correlated with phonon wavelengths.

6.1 Copper Alloys

From the <u>Cu</u>-10 at. % Al and <u>Cu</u>-30 at. % Zn alloy results shown in Fig. 4 and Fig. 5 respectively, we observe:-

- (i) A change in the temperature dependence of λ around 2.5 to 3 K, referred to as the "kink".
- (ii) An excess conductivity appears below 1.2 K
 referred to as a "bump".
- (iii) Annealing successively at higher temperatures increases the lattice conductivity but the fractional increases in λ_g at the lowest temperatures are much smaller than at 4 K.

TV GUPGAHS

DISCUSSION OF MODELS AND EXPERIMENTAL RESULTS

The thermal conductivity results of copper allova will first be discussed. In section 6.1 it a chown that the anomalies lie in Ngd (phonon scattering by disclositions) and in section (.2 the copper alloy care is discussed with reference to various existing models.

Results for the silvex and gold alloys are discussed in section 6.3 and finally, in section 6.4, the temperatures at which the anomalies occur are correlated with phonon wavelengths.

Prom the Cu-10 at. % Al and Cu-30 at. v Zn alloy results shown in Fig. 4 and Fig. 5 respectively, we observe:-

A change in the temperature dependence of around 2.5 to 3 K, referred to as the "kink" An excess conductivity appears below 1.2 K referred to as a "bun ".

It will first be shown that all these anomalies lie in the lattice component $\lambda_{\rm g}$. They cannot arise from the electronic component $\lambda_{\rm e}$, as any changes in $\lambda_{\rm e}$ would be reflected as changes in the electrical resistivity of the specimen through the Weidemann-Franz Law, eqn. (2.2). The electrical resistivity of both the Cu-Al and Cu-Zn alloys was measured, and found to be constant to within 1/2%, over the temperature range 0.5 to 4 K. Therefore, unless a conduction process in addition to phonons and electrons is present, the anomalies must be in $\lambda_{\rm g}$.

6.1.1 Scattering of phonons by electrons or defects?

Having shown that the anomalies are in λ_g the question arises whether they are in W_{gd} (phonon scattering by defects) or W_{ge} (phonon scattering by electrons)? The author believes the kink to be a change in phonon scattering by defects. In Fig. 4 the annealed alloy has the largest λ_g , implying smallest W_{gd} . However, the kink is absent. The kink is present in partially annealed alloys and is more pronounced in the specimen with greater cold-work i.e. larger W_{gd} . The most coldworked specimen is apparently an exception since it has no kink. In this case, however, the slope is so small that the presence or absence of a kink is unobservable. The author, therefore, disagrees with

I wil tirst is above that all those anomatics also in the lartee downpropent \(\lambda_q \). They cannot arise from the electronic component \(\lambda_q \) as any changes in the electrical rest would be reflected as changes in the electrical rest tivity of the specimen through the Weidemann-F; the eqn. (2.2), the electronic largestropy as measured and found to constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the tempera in the constant to within 1/2 over the constant to the

believes the kink to b. chance
to ing by defects. In Pig. 4 the annealed listy
s the largest k, implying smallest Wqd. However,
kink is absent. The kink is present in partially
cancaled alloys and is more pronounce in the specime

Mitchell et al (1971) who ascribed the kink to $W_{\rm ge}$. Although other large scale defects, which anneal out of cold-worked specimens, could account for these results and the results of other authors above 1.5 K, dislocations seem likely to dominate the phonon scattering in cold-worked specimens (Klemens 1958).

Below 1.2 K the thermal conductivity points lie above the line extrapolated from high temperature measurements (Fig. 4 and Fig. 5). This excess conductivity is also believed to be a feature of W and not W_{qe} . Since λ_q in the cold-worked state is very much smaller than in the annealed state, Wqd >> Wqe in the cold-worked state. The excess conductivity persists in the cold-worked state indicating that the bump is a component of W_{qd} and is interpreted as a non-standard decrease in Wad below 1.2 K. The interpretation is not so straightforward in the annealed alloys since the relative size of W_{qe} and W_{qd} is unknown and the former could also be anomalous. The simplest explanation is that the anomalies are in W_{qd} in all states of anneal. This makes it necessary to assume that even in the fully annealed state, $W_{\mbox{\scriptsize qd}}$ is still of measurable size and has a similar temperature dependence as for the cold-worked state. Below 0.7 K, λ/T curves are a much less rapid function of cold-work than above 1.5 K. This suggests that below 0.7 K, W_{α} for the fully annealed Mitchell et al (1871) who secribed the kink to was "Although other large scale defects, which anneas one of cold-worked specimens, could account for these results and the results of other authors above 1.3 K, dislocations seem likely to deminate the phon: scattering in cold-worked specimens (Klemen: 183

lie above the line extrapolated from any temperature measum ements (Fig. 4 and Fig. 5). This ess nower tivity is also believed to be a feature of and measure in the cold-worked state is smaller than in the annear a state, G. 7 W. and cold-worked state. The excess conductivity nersure in the cold-worked state indicating that the bump is a copenent of W. and is interpreted as a non-standard decrease in W. below 1.2 K. The interpretation is not so straightforward in the annealed alloys since the could also be anomalous. The simples: explanation is that that the anomalous. The simples: explanation is that that the anomalous in M. and I states of anneal.

rsikmi

alloys should be a good estimate for W_{ge} . Previous estimates of W_{ge} , based on data above 1.5 K, would thus be too large.

6.1.2 Estimates of electron limited lattice conductivity

In section 2.2.1 it was shown that the electron limited lattice thermal conductivity, $\lambda_{\rm e}$, is proportional to T^2 at low temperatures. Klemens (1958) has calculated W_{qe} T^2 for pure copper and shown that it should be fairly constant on alloying. In Fig. 10 the observed values of $W_{q}T^{2}$ for <u>Cu-Zn</u> alloys, pure copper, and a single Cu-Fe alloy, obtained from a number of sources, are shown plotted against impurity concentration. It is evident from this figure that $W_{\rm g}T^2$ obtained from Kemp et al (1957) increases with concentration and the reasons for this are controversial. White and Woods (1954) evaluated W_{α} T^2 for a <u>Cu-0.056</u> at. % Fe specimen and obtained a value in close agreement with the theoretical value of W_{qe} T² (Klemens 1958). The values of $W_q T^2$ obtained from the annealed <u>Cu-Zn</u> alloy and single crystal reported here, (in the region 1-4 K) are approximately the same as those of Kemp et al (1957), for similar concentrations. However, values of WgT2, evaluated by extrapolating the few measurements below 0.7 K through L ± 1%, give an estimate of

 W_{ge} , are much closer to the value in pure copper, as might be expected from the arguments presented above.

6.1.3 Brass single crystal

Having shown that the anomalies probably arise due to changes in phonon-dislocation scattering, a brass (Cu-30 at. % Zn) single crystal with a low concentration of dislocations (see section 7.2) was measured. Fig. 6 shows that the bump persists and is similar to that in the annealed polycrystalline specimen (Fig. 5). This result is in agreement with measurements of Salter and Charsley (1967) above 1.5 K, on a Cu-12 at. % Al single crystal which has had a lattice conductivity similar to an annealed polycrystalline sample of the same concentration.

6.2 Existing Models

As pointed out in Chapter II, various models have been proposed to explain the anomalous behaviour in λ_g of copper alloys (of comparable ρ_o) around 2-3 K, and predictions have been made of enhanced conductivities in the 3 He region. Two categories of models, already described in Chapter II, involve phonon scattering by either (a) static dislocations or (b) mobile dislocations. We will first discuss our data in terms of the static

, are much closer to the rates in pure capper, as might be expected final the arguments presented above.

-6.2 Existing Models

As pointed out in Chapter II, various models have been proposed to explain the anomalous behaviour in A of copper alloys (of compar his p) around 2-1 K, and the s have been made of enhanced conductivities

dislocation model.

6.2.1 Static dislocations

(a) Dipole model

Leaver and Charsley (1971) have calculated the temperature dependence of $\boldsymbol{\lambda}_{\boldsymbol{\sigma}}$ using the dislocation dipole model. They had evidence from electron microscope data, that in their Cu-Al and Cu-Zn specimens, only 20% of the dislocations were in dipole configuration and the dislocation separation, d, for these dipoles was ≈200 Å. Following their method of analysis, detailed computer calculations were made by varying a parameter n and choosing different values for d (100 to 300 Å). Over the temperature range 1.2 to 4 K, there is fairly good agreement between the calculated curves and our experimental data. However, below 1.2 K, the calculated λ_{σ} values lie much below the experimental values. was found that slightly better agreement was obtained below 1.2 K, if a greater fraction of dislocations were assumed to be in dipole formation. However, although the λ_q/T vs T plots appear to be of the right form, and some modification may fit the data exactly, the Leaver and Charsley model, with realistic parameters, cannot explain the enhanced conductivities.

.2.1 Static dist ration

a Dipole model

Leaver and Charsle 1971

(b) Dislocation rearrangement model

On the basis of their dislocation rearrangement model, Ackerman and Klemens (1971) have shown that the onset temperature, T_B , of excess conductivities in the $^3\mathrm{He}$ region depends on (a) the ratio of the lattice conductivity in the annealed state to that in the deformed state and (b) the density of dislocations in the deformed state N_d . Calculations using $N_d\approx 10^{11}$ cm $^{-2}$ and λ_g (annealed)/ λ_g (deformed) \approx 3 yield $T_B\sim 1.2$ K. On annealing, N_d decreases and T_B should also decrease. It is evident from the results on Cu-Al and Cu-Zn (Fig. 4 and Fig. 5) that T_B is independent of dislocation densities in contradiction to the predictions of Ackerman and Klemens (1971).

6.2.2 Mobile dislocations

Both the models discussed above lead to a reduction in phonon-dislocation scattering, and thereby an increase in the lattice conductivity, when the phonon wavelengths become larger than some critical value.

Two other models, (based on vibrating dislocations) have also been proposed -- (a) scattering of phonons by mobile dislocations (Ziman 1960) and (b) resonant scattering of phonons by vibrating partial dislocations (Kronmüller 1972).

(b) Dislocation rearrandement model

On the passe of their firemating (1971) have shown not model, exerman and elements (1971) have shown not made transcribility. Of modes contact was a firemate transcribility in the annealed state to the the conductivity in the annealed state to the deformed state and (b) the density of an eventual of an element of the deformed state Na. 6.2.2 Mobile dislocations

Both the models discussed above lead to: TLG_S
ion in honor slocat on scatteri
increase in the lattice conductivity, when an , nonce
wavelengths become larger than some critical value.
Two other models, (based o vibrating dislocations)
ilso been proposed -- (c

- (a) Ziman (1960) has shown that the scattering of phonons by mobile dislocations leads to $W_{\rm gd} \propto T^{-4}$ i.e. $\lambda_{\rm g} \propto T^4$, at low temperatures. For all the data plotted, at no point in the temperature range 0.5 to 4 K does the lattice conductivity have this strong a temperature dependence.
- (b) More recently, Kronmüller (1972) has calculated the vibrational frequencies of partial dislocations in cold-worked, face-centred cubic metals. These frequencies correspond to dominant phonon frequencies around 1 K so that resonant scattering may occur. Resonant scattering of phonons is observed as a change in the temperature dependence of the lattice conductivity, at a temperature corresponding to the resonant frequency ω_{o} . Kronmüller has also shown that there should be two such frequencies, one for partial edge dislocations and another, at approximately twice the frequency for partial screw dislocations. In a given alloy, ω_{o} is related to the stacking fault energy γ by eqn. (2.7) so that copper alloys with different stacking fault energies should show resonant scattering at different temperatures. Values of stacking fault energies obtained from Saada (1966) show that γ (Cu-30 at. % Zn)/ γ (Cu-10 at. % Al) \approx 2 so that $T_{R}(\underline{Cu}-30 \text{ at. } \% \text{ Zn})/T_{R}(\underline{Cu}-10 \text{ at. } \% \text{ Al})$ and $T_k (\underline{Cu}-30 \text{ at. } \% \text{ Zn})/T_k (\underline{Cu}-10 \text{ at. } \% \text{ Al}) \text{ should be } \approx 2.$ However, from the results on Cu-Al and Cu-Zn alloys

ions, In caven alic

's with different stackin fault energies should show quenent scatter of at different ter eratures.

(Fig. 4 and Fig. 5) it is evident that T_B is 1.2 K and $T_k \sim 3$ K for both alloys, which is evidence that Kronmüller's mechanism is not responsible. Further evidence is supplied by comparing the thermal conductivity of a cold-worked Cu-2 at. % Al alloy (Salter and Charsley 1967) with the results on Cu-10 at. % Al reported here. Although the two alloys have widely different stacking fault energies (Saada 1966), the temperature of the kink (≈ 3 K) is the same for both specimens.

Anomalies in λ_{σ} , of the same order of magnitude as the bumps reported here, have been observed in potassium chloride (Pohl 1962), superconducting niobium (Anderson et al 1973) and in some copper alloys (Linz et al 1974), and have been associated with the resonant scattering of phonons. Linz et al (1974) are the only group who have reported a definite minimum in λ_{σ} . Determining the presence or absence of minima in λ_{σ} is important as only Kronmüller's model can explain a minimum in $\lambda_{_{\mbox{\scriptsize G}}}$ at around 1 K. The shape of $\lambda_{_{\mbox{\scriptsize G}}}$ against T plots is strongly dependent on the accuracy of the experimental Lorenz number, L. In our heavily coldworked specimens, a shift of L by ±1 % can either introduce or eliminate a minimum in λ_{σ} . For all other states of anneal, where, because λ_{q} is a larger proportion of λ , the accuracy of L is not so critical, no minimum is observed.

(Piq. 4 and Fig. 3) it is evident that The in 1.2 m and the committee mechanism is not responsible authorism is not responsible authorism is not responsible authorism in the conformation of the conformation

tios In

Thermal conductivity results of Linz et al (1974) are different, on this point, in that they observe a minimum in the lattice conductivity of copper alloys, in all states of anneal, around 1 K. It is the author's opinion that it is outside the range of the state-of-the-art to be certain that minima do exist in the cold-worked alloys. However, our results for the partially and fully annealed alloys are accurate enough to eliminate the possibility that minima exist. Further work is probably necessary to resolve the difference.

6.2.3 Summary

Following the discussion on static dislocation models in section 6.2.1, it can be concluded that neither the dislocation-dipole model (Leaver and Charsley 1971) nor the dislocation-rearrangement model (Ackerman and Klemens 1971) can adequately explain our results. Of the two mobile dislocation models, it has been shown that the one proposed by Ziman (1960) is not applicable to the results reported here. The other model (Kronmüller 1972) is the only one that can explain the presence of a minimum in the lattice conductivity, though stacking fault energy considerations show even this model to be inconsistent with our data. It is concluded therefore that none of the models discussed so far can adequately

explain our results. However the anomalies were determined to be in $\lambda_{\rm g}$ and associated with changes in dislocation scattering. Although the Leaver and Charsley (1971) model does not fit our data, it is believed that some modification of their model can produce a much better fit. The main feature is the assumption of a "characteristic" length, of the order of a few hundred angstroms, associated with the dilocation structure.

6.3 Silver and Gold Alloys

From the arguments in section 6.2 it was concluded that the λ_g anomalies in copper alloys were due to changes in the phonon-dislocation scattering, involving a characteristic length. This conclusion was tested by measurements on other noble metal hosts, where, due to changes in the Debye temperature, phonon wavelengths and dislocation vibrational frequencies would be different and so the anomalies in λ_g would occur at different temperatures.

For each silver and gold alloy specimen, measurements were made only in highly cold-worked and fully annealed states. The temperature of the kink, T_k , for the Ag-2.1 at. % Al (Fig. 7) is roughly ~2.5 K and T_B , the onset temperature of the excess conductivity is 1 K.

Por each silver and gold a

The presence of a slight kink around 2.5 K for the fully annealed specimen is probably due to the annealing temperature not being sufficiently high. For the gold alloys (Fig. 8 and Fig. 9), T_k is ~2 K and measurements do not extend to a low enough temperature to show a complete bump, since T_B is below 0.8 K. The arguments which have been used to determine the cause of the kink and the excess conductivity bump in copper alloys also apply to the silver and gold alloys. Thus we concluded that the anomalies in all the alloys occur in $W_{\rm gd}$ (scattering of phonons by dislocations).

For the cold-worked gold alloys the measured Lorenz number, at certain temperatures, had a value less than the classical value of $2.445 \times 10^{-8}~\rm W\Omega K^{-2}$. Consequently when λ_g was calculated, using eqn. (5.1), negative values for λ_g were obtained, at those temperatures. This can be regarded as an extreme case of a minimum and can be explained, as before, as a cumulative error affecting the lattice conductivity. The Au-2 at. % Pt alloy was measured first in the coldworked state and the calculated λ_g values (using eqn. (5.1)) were all positive. After annealing and rerolling it was found that the residual resistivity had increased by a factor of two and λ_g values decreased proportionately. The lattice conductivity values at some temperatures were now negative but the shape of

 λ/T against T plots was the same so that both T_k and T_B were unaffected. It is possible that a mistake was made in measuring ρ_Ω in the re-rolled state.

6.4 "Effective" Phonon Wavelengths

The apparent similarity of λ_g for alloys with the same host and the difference between alloys with different hosts can be explained by considering the phonon wavelengths in the hosts. Carruthers (1961) defines an "effective wavelength $\bar{\lambda}$ characterizing those phonons most important in conduction at low temperatures by

$$\bar{\lambda} = 0.6 \text{ d (0/T)} \tag{6.1}$$

where d is the lattice constant and 0 the Debye temperature of the lattice. Values for these quantities are listed in Table 19. It may be observed that the effective wavelength is nearly the same in copper, silver and gold at $T_{\rm B}$, the temperature immediately below which the excess conductivity appears. The temperature of the kink, $T_{\rm k}$, changes in a similar manner to $T_{\rm B}$ but since $T_{\rm k}$ is less well defined than $T_{\rm B}$ a quantitative estimate has not been made. The systematic change in $T_{\rm B}$ and $T_{\rm k}$ is further evidence that the lattice conductivity is involved and that the conductivity is limited by scattering centres, characterized by the same separation in each metal investigated.

CHAPTER VII

SUGGESTIONS FOR FURTHER WORK

There are three areas in which preliminary investigations have produced interesting results:

- (a) Superconductors
- (b) Electron Microscopy
- (c) Amorphous Materials.

Since the work described here is preliminary, the suggestions made in this chapter are of a speculative nature compared to the rest of the thesis. It is hoped that the following discussion will give direction to further research in the study of phonon-defect scattering.

7.1 Superconductors

In a superconducting alloy, as the temperature is reduced below the critical temperature $T_{\rm C}$, some of the electrons condense into the superconducting ground state. These electrons neither carry heat nor scatter phonons resulting in: (a) a decrease in the electronic conductivity, $\lambda_{\rm e}$ and (b) a decrease in $W_{\rm ge}$ thereby increasing the lattice conductivity, $\lambda_{\rm g}$. Consequently, at a temperature $T \stackrel{\sim}{<} 0.2~T_{\rm C}$, it may be assumed that the

total measured thermal conductivity is due to phonon conduction limited by scattering from defects.

Measurements made by Anderson and Smith (1973) on single crystal niobium samples exhibited anomalous lattice conductivities between 0.1 and 2 K. They attributed their results to the resonant scattering of phonons by mobile dislocations because the mean free path of phonons passed through a minimum at a temperature near 0.5 K.

One could choose various superconducting materials, with different stacking fault energies and Debye temperatures, and put them to the same series of tests as the noble metal alloys. It would then be interesting to see if correlations existed between the temperatures of the anomalies and values of Debye temperatures or stacking fault energies of the alloys.

7.2 Electron Microscopy

Following the arguments in section 6.1, it seems that all the anomalies in our results could be explained on the basis of phonon scattering by dislocations and their associated strain fields. Table 19 indicates that the "characteristic" length associated with the dislocation structure, in all the alloys, should be of the order of a few hundred angstroms. Consequently, a preliminary investigation of the dislocation structure in

total messured thermal conductivity is due to phonon

the specimens reported here, was made with the electron microscope.

In collaboration with the Physics Department electron microscopy group, specimens of the annealed copper alloys were prepared and studied under the microscope. This investigation was limited to a single sample of each specimen and failed to show any dislocation structure necessary to explain our results. In the brass single crystal the dislocation density was $<10^8$ cm⁻² and the annealed Cu-10 at. % Al alloy had a dislocation density of the same magnitude. The annealed Cu-30 at. % Zn alloy showed an extremely high density of dislocation. This was probably not characteristic of the bulk specimen but due to the considerable problems involved in preparing a specimen for electron miscroscopy. However, other interesting features were observed in both the Cu-10 at. % Al and the brass single crystal and these are shown in Fig. 11. These electron micrographs show surface variations of the sample thickness, which is indicative of preferential etching, in regions of ~100-500 Å. This suggests the presence of a microstructure of a few hundred A which could lead to anomalous scattering for phonons of ~100-500 Å wavelength.

7.3 Amorphous Materials

Zeller and Pohl (1971) measured the thermal

the specimens reputred here, was made with the electron

conductivity of some amorphous materials in the temperature range 0.05 to 100 K and their results, for Pyrex and selenium, along with our data on Cu-10 at. % Al, are presented in Fig. 12. The lattice conductivity of both the amorphous materials and the copper alloy is of the same order of magnitude and all the curves have the same characteristic shape with a plateau, though those for the copper alloy are much narrower and at a lower temperature. Morgan and Smith (1974) proposed a very general model of phonon scattering by structural disorder to explain the experimental results on amorphous materials. Their model contains two correlation lengths associated with some order in the solid. Their calculations show that $\boldsymbol{\lambda}_{\sigma}$ decreases approximately as T² in two regions separated by a plateau as shown in Fig. 12. With correlation lengths of 10 Å and 1000 Å they obtained results similar to those for the amorphous materials but longer range correlations would shift the plateau to lower tempera-It is possible that the similarity of results for noble metals and amorphous materials may not be entirely fortuitous. Hopefully, there will emerge a very general model to explain the behaviour of lattice conductivity in a variety of materials, at low temperatures.

CHAPTER VIII

CONCLUSIONS

Measurements of the thermal conductivity λ of deformed alloys of copper, silver and gold confirmed the presence of a non-linearity or kink in λ/T vs T plots near 3 K. In the copper and gold alloys, this kink disappeared when the specimens were sufficiently annealed. There was no evidence of any temperature variation of the electrical resistivity in these alloys below 4 K. It is therefore concluded that the kink arose in the lattice conductivity and that it must have been the result of scattering processes that were diminished by annealing.

An excess thermal conductivity, above that expected, occurred in each of these alloys below a temperature T_B near 1 K. Although annealing did not remove this excess conductivity it was also ascribed to a decrease of the phonon scattering by defects below T_B . Both the temperature of the kink and bump varied with the host metal of the alloy which suggests that the anomalies in λ_g are associated with phonons of the same wavelength in all noble metal hosts.

Preliminary electron microscope measurements on copper alloys do not indicate the presence of a dislocation structure with an associated "characteristic"

APPENDIX II

ADDITIVITY OF THERMAL RESISTANCES

In Section 2.2.2 the total lattice thermal resistance was calculated by adding the thermal resistances W_{ge} (phonon-electron scattering) and W_{gd} (phonon-defect scattering). This procedure is valid only if the scattering processes have the same frequency dependence. If phonon-scattering processes with different frequency dependence are present simultaneously they must be combined by adding the appropriate reciprocal relaxation times before integrating over all frequencies. The relation to be used is then of the form:

$$\lambda_g = AT^3 \int [1/(\frac{1}{\tau_E} + \frac{1}{\tau_D})] \frac{x^4 e^x}{(e^x - 1)^2} dx$$

where x \equiv hv/kT and depends on fundamental constants and the velocity of sound. The relaxation times τ_E and τ_D are for phonon scattering by electrons and by defects respectively (Lindenfeld 1966).

Pippard (1957) has shown that for impure metals at low temperatures (when $ql \sim 1$) the lattice conductivity does not follow a simple T^2 dependence but may be approximated by

$$\lambda_g = AT + BT^2$$
.

Car Share of the

Plotted on a universal curve (Fig. 13), λ_g should follow a T² dependence for large T/ ρ_o (ql>1) but change over to a linear temperature dependence for small values of T/ ρ_o (ql<1). Since all our measurements lie in the region where ql~1 it is important to see if the anomalies can be explained by the extra conductivity arising from the linear term.

Data for the annealed copper alloys are plotted in Fig. 13 as $\lambda_{\rm g}/{\rm T}\rho_{\rm o}$ vs T/ $\rho_{\rm o}.$ The dotted line represents the theoretical curve for copper as calculated by Lindenfeld (1962). In the region 1-4 K the data lie below the theoretical curve implying that some defect scattering still exists in the annealed specimens. At 1.2 K $\lambda_{\rm g}$ rises sharply above the theoretical limit which makes one conclude that the increase in $\lambda_{\rm g}$ cannot be explained by the "Pippard effect" in W $_{\rm ge}$ as the dotted line represents the limiting value for W $_{\rm ge}$ and yet the experimental results rise above it and the change in $\lambda_{\rm g}$ is too abrupt.

In the fully cold-worked alloy the arguments are unchanged even if $W_{\rm ge}$ and $W_{\rm gd}$ have different frequency dependence, because $W_{\rm gd}$ >> $W_{\rm ge}$ at all temperatures, which is all that is necessary for our conclusions to follow.
